

Popular: beauty as discipline, wide applicability Started in 2D with linear objects (points, lines,...), now 3D and nD, hyperplanes, curved objects,... Shift from purely mathematical approach and asymptotical optimality ignoring singular cases to practical algorithms, simpler data structures and robustness => algorithms and data structures provable efficient in realistic situations (application dependent)

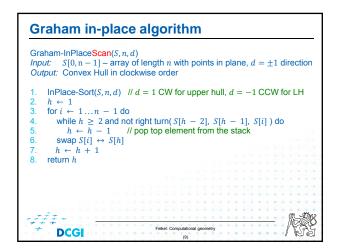

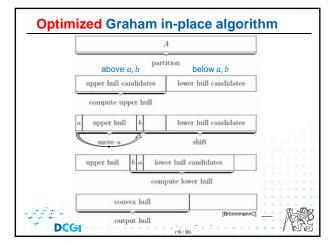

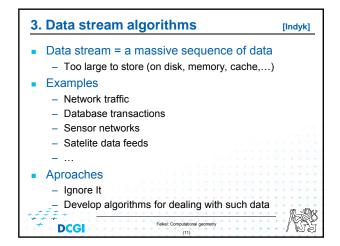

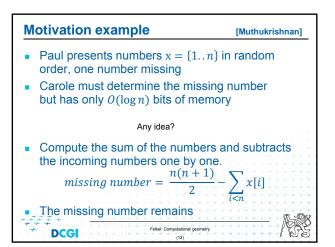

Graham in-place algorithm Graham-InPlaceHull(S,n) Input: S – an array of length n with points in plane Output: Convex Hull in clockwise order 1. $h \leftarrow$ Graham-InPlace-Scan(S,n, 1) // CW upper hull 2. for $i \leftarrow 0 \dots h - 2$ do 3. swap $S[i] \leftrightarrow S[i+1]$ // bubble a to the right 4. $h' \leftarrow$ Graham-InPlace-Scan(S+h-2,n-h+2,-1) // lower hull 5. return h+h'-2Stack at the beginning of the array

Motivation example

[Muthukrishnan]

- And two missing numbers?
- Store sum of numbers s and sum of squares s'

$$i+j=\frac{n(n+1)}{2}-s$$

$$i^2 + j^2 = \frac{n(n+1)(2n+1)}{6} - s'$$

utational geometry

Basic data stream model

[Indyk]

- Single pass over the data: a_1, a_2, \dots, a_n
 - Typically n is known
- Bounded storage (typically n^{α} or $\log^{c} n$ or only c)
 - Units of storage: bits, words, or elements (such as points, nodes/edges, ...)
 - Impossible to store the data
- Fast processing time per element
 - Randomness is OK (in fact, almost necessary)

Felkel: Computational geometr

Data stream models classification

- Input stream *a*₁, *a*₂, ..., *an*
 - arrives sequentially, item by item
 - describes an underlying signal A,
 a 1D function A: [1..N] -> R
- Models differ on how a_i's describe the signal A (in decreasing order of generality):
 - a) Time series model $-a_i$ equals A[i], in increasing i
 - b) Cash register model a_i are increments to A[j], Ii > 0
 - c) Turnstyle model $-a_i$ are updates to $A[j], U_i \in R$

Felkel: Computational geometry (15)

a) Time series model (Časová řada)

- Stream elements a_i are equal to A[i] (samples of the signal)
- a_i's appear in increasing order of i
- Applications
 - Observation of the traffic on IP address each 5 minutes
 - NASDAQ volume of trades per minute

lkel: Computational geometry

b) Cash register model (registrační pokladna)

- a_i are increments to A[j]'s
- Stream elements $a_i = (j, Ii), I_i \ge 0$ to mean

$$A_i[j] = A_{i-1}[j] + Ii$$

where

- A_i is the state of the signal after seeing i-th item
- multiple a_i can increment given A[j] over time
- A most popular data stream model
 - IP addresses accessing web server
 - Source IP addresses sending packets over a link
 - access many times, send many packets,...

elkel: Computational geometry

c) Turnstile model (turniket)

- a_i are updates to A[j]'s
- Stream elements $a_i = (j, U_i), I_i \in R$ to mean

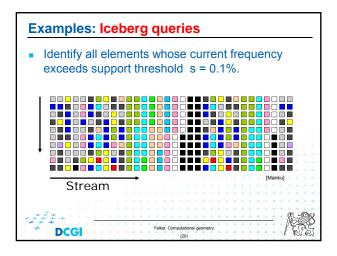

$$A_i[j] = Ai \quad {}_1[j] + U_i$$

where

- A_i is the state of the signal after seeing i-th item
- *U_i* may be positive or negative
- multiple a_i can updategiven A[j] over time
- A most general data stream model
- Passengers in NY subway arriving and departing
- Hard to get reasonable solution in this model

c) Turnstile model variants (for completness) ■ strict turnstile model $-A_i[j] \ge 0$ for all i- People can only exit via the turnstile they entered in Databases – delete only a record you inserted - Storage - you can take items only if they are there non-strict turnstile model – $A_i[j] < 0$ for some i Difference between two cash register streams

Ex: Iceberg queries – a) ordinary solution

The ordinary solution in two passes

- 1. Pass identify frequencies
 - a set of counters is maintained. Each incoming item is hashed onto a counter, which is incremented.
 - These counters are then compressed into a bitmap, with a 1 denoting a large counter value.
- 2. Pass count exact values
 - exact frequencies for only those elements are maintained which hash to a value whose corresponding bitmap value is 1
- Hard to modify for datastream unknown frequencies after only 1st pass

DCG

Ex: Iceberg queries - problem definition

- Input: threshold $s \in (0,1)$, error $\varepsilon \in (0,1)$, length N
- Output: list of items and frequencies

- Guarantees:
 - No item omitted (reported all items with frequency > sN)
 - No item added (no item with frequency $< (s \epsilon)N$)
 - Estimated frequencies not less than ϵN of the true frequencies
- **EX**: s = 0.1%, $\epsilon = 0.01\% \epsilon$ about $\frac{1}{10}$ to $\frac{1}{20}$ of s
 - All element with freq. > 0.1% will output
 - None of element with freq. < 0.09% will output

Some elements between 0.09% and 0.1% will output

Ex: Iceberg queries – b) sticky sampling

- Probabilistic algorithm, given threshold s, error ϵ and probability of failure δ
 - Data structure S of entries (e, f), e element, f estimated frequency, r sampling rate, sampling probability ¹/₋
- $S \leftarrow \emptyset, r \leftarrow 1$
- If $e \in s$ then (e, f++)

else insert (e, f) into S with probability $\frac{1}{a}$

 S sweeps along the stream as a magnet, attracting all elements which already have an entry in S

DCGI

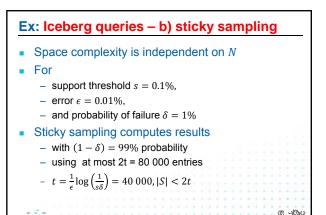

Ex: Iceberg queries – b) sticky sampling

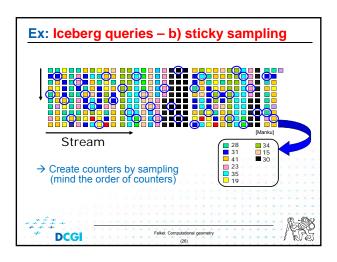

- r changes over the stream, $t = \frac{1}{\epsilon} \log \left(\frac{1}{\epsilon \delta} \right)$, |S| < 2t
 - 2t elements r = 1
 - next 2t elements r = 2
 - next 4t elements $r = 4 \dots$
- whenever r changes, we update S
 - For each entry (e, f) in S
 - toss a coin until successful (head)
 - ullet if not successful (tail), decrement f
 - if f becomes 0, remove entry (e, f) from S

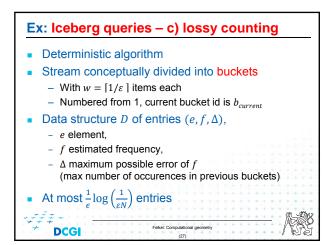

Output: list of items with threshold s i.e. all entries in S where $f \ge (s - \epsilon)N$

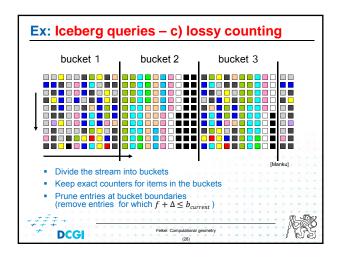

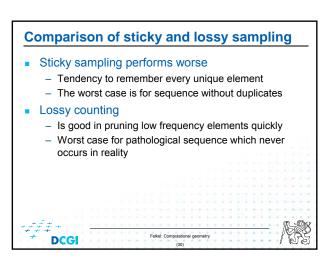

DCG

Ex: Iceberg queries — c) lossy counting alg. Description P(x)New element P(x)If P(x)Represent the sum of the property of the sum of t

Number of mutually different entries

- Input: stream $a_1, a_2, ..., an$, with repeated entries
- Output: Estimate of number of different entries
- Appl: # of different transactions in one day
- Precise deterministic algorithm:
 - Array b[1..U], $U = \max$ number of different entries
 - Init by b[i] = 0 for all i, counter c = 0
 - For each a_i
 - if $b[a_i] = 0$ then inc(c), b[i] = 1
 - Return c as number of different entries in b[]
 - O(1) update and query times, O(U) memory

Felkel: Computational geometry

Number of mutually different entries

- Approximate algorithm
 - Array $b[1..\log U]$, $U = \max$ number of different entries
 - Init by b[i] = 0 for all i, counter c = 0
 - Hash function h: {1..U} → {0..log U}
 - For each a_i
 - Set b[h(ai)] = 1
 - Extract probable number of different entries from b[]

Felkel: Computational geometry

Sublinear time example

- Given mutually different numbers $a_1, a_2, ..., an$
- Determine number in upper half of values
- Alg: select k numbers equally randomly
 - Compute their maximum
 - Return it as solution
- Probability of wrong answer = probability of all selected numbers are from the lower half = $\left(\frac{1}{2}\right)^k$
- For error δ take $\log \frac{1}{\delta}$ samples
- Not useful for MIN, MAX selection

Felkel: Computational geometry (33)

4. Randomized algorithms

Motivation

- Array of elements, half of char "a", half of char "b"
- Find "a"
- Deterministic alg: n/2 steps of sequential search (when all "b" are first)
- Randomized:
 - Try random indices
 - Probability of finding "a" soon is high regardless of the order of characters in the array (Las Vegas algorithm)

Felkel: Computational geometry

Randomized algorithms

- May be simpler even if the same worst time
- We do not know a deterministic version (prime numbers)
- Deterministic algorithm does not exist
- Randomization can improve the average running time (with the same worst case time), while the worst time depends on our luck – not on the data distribution

Felkel: Computational geometry

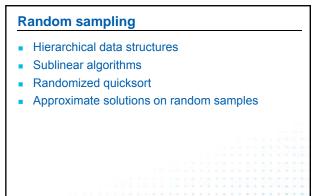

Randomized algorithms

- a) Incremental algorithms
 - Linear programming see seminars
 - Convex hulls
 - Intersections, space subdivisions
- b) Divide and conquer
 - Random sampling
 - Nearest neighbors, trapezoidal subdivisions
