

► Matching Table

Based on scene opacity and the observation on mutual exclusion we expect each pixel to match at most once.

matching table

- rows and columns represent optical rays
- nodes: possible correspondence pairs
- full nodes: matches
- numerical values associated with nodes: descriptor similarities

[see next](#)

► Constructing A Suitable Image Similarity Statistic

- let $p_i = (l, r)$ and $\mathbf{L}(l)$, $\mathbf{R}(r)$ be (left, right) image descriptors (vectors) constructed from local image neighborhood windows

$$\rho = \frac{\text{cov}(x, y)}{\sqrt{\text{var}(x) \cdot \text{var}(y)}}$$

'block' in the left image:

- a simple block similarity is $\text{SAD}(l, r) = \|\mathbf{L}(l) - \mathbf{R}(r)\|_1$ L_1 metric (sum of absolute differences)
- a scaled-descriptor similarity is $\text{sim}(l, r) = \frac{\|\mathbf{L}(l) - \mathbf{R}(r)\|^2}{\sigma_I^2(l, r)}$ smaller is better
- σ_I^2 – the difference scale; a suitable (plug-in) estimate is $\frac{1}{2} [\text{var}(\mathbf{L}(l)) + \text{var}(\mathbf{R}(r))]$, giving

$$\text{sim}(l, r) = 1 - \frac{2 \text{cov}(\mathbf{L}(l), \mathbf{R}(r))}{\underbrace{\text{var}(\mathbf{L}(l)) + \text{var}(\mathbf{R}(r))}_{\rho(\mathbf{L}(l), \mathbf{R}(r))}} \quad \text{var}(\cdot), \text{cov}(\cdot) \text{ is sample (co-)variance} \quad (34)$$

- ρ – MNCC – Moravec's Normalized Cross-Correlation statistic bigger is better [Moravec 1977]
 $\rho^2 \in [0, 1]$, sign $\rho \sim$ 'phase'

How A Scene Looks in The Filled-In Matching Table

- MNCC ρ used ($\alpha = 1.5, \beta = 1$)
- high-correlation structures correspond to scene objects

- **constant disparity**
- a diagonal in matching table
- zero disparity is the main diagonal **nonstd rectification**

- **depth discontinuity**
- horizontal or vertical jump in matching table

- **large image window**
- better correlation
- worse occlusion localization

- **repeated texture**
- horizontal and vertical block repetition

a good tradeoff occlusion artefacts undiscriminable

Image Point Descriptors And Their Similarity

Descriptors: Image points are tagged by their (viewpoint-invariant) physical properties:

- texture window
- a descriptor like DAISY
- learned descriptors
- reflectance profile under a moving illuminant
- photometric ratios
- dual photometric stereo
- polarization signature
- ...

[Moravec 77]

[Tola et al. 2010]

[Wolff & Angelopoulou 93-94]

[Ikeuchi 87]

- similar points are more likely to match
- image similarity values for all 'match candidates' give the 3D matching table

video

► Marroquin's Winner Take All (WTA) Matching Algorithm

1. per left-image pixel: find the most similar right-image pixel using SAD →164
2. select disparity range this is a critical weak point
3. represent the matching table diagonals in a compact form

4. use an 'image sliding & cost aggregation algorithm'

5. take the maximum over disparities d
6. threshold results by maximal allowed SAD dissimilarity

A Matlab Code for WTA

```
function dmap = marroquin(impl,imr,disparityRange)
%       impl, imr - rectified gray-scale images
% disparityRange - non-negative disparity range

% (c) Radim Sara (sara@cmp.felk.cvut.cz) FEE CTU Prague, 10 Dec 12

thr = 20;           % bad match rejection threshold
r = 2;
winsize = 2*r+[1 1]; % 5x5 window (neighborhood) for r=2

% the size of each local patch; it is  $N=(2r+1)^2$  except for boundary pixels
N = boxing(ones(size(impl)), winsize);

% computing dissimilarity per pixel (unscaled SAD)
for d = 0:disparityRange           % cycle over all disparities
    slice = abs(imr(:,1:end-d) - impl(:,d+1:end)); % pixelwise dissimilarity
    V(:,d+1:end,d+1) = boxing(slice, winsize)./N; % window aggregation
end

% collect winners, threshold, and output disparity map
[cmap,dmap] = min(V,[],3);
dmap(cmap > thr) = NaN; % mask-out high dissimilarity pixels
end % of marroquin

function c = boxing(im, wsz)
% if the mex is not found, run this slow version:
c = conv2(ones(1,wsz(1)), ones(wsz(2),1), im, 'same');
end % of boxing
```

WTA: Some Results

thr = 20

thr = 10

- results are fairly bad
- false matches in textureless image regions and on repetitive structures (book shelf)
- a more restrictive threshold (thr = 10) does not work as expected
- we searched the true disparity range, results get worse if the range is set wider
- chief failure reasons:
 - unnormalized image dissimilarity does not work well
 - no occlusion model (it just ignores the occlusion structure we have discussed →162)

► A Principled Approach to Similarity

Empirical Distribution of MNCC ρ for Matches and Non-Matches

- histograms of ρ computed from 5×5 correlation window
- KITTI dataset
 - $4.2 \cdot 10^6$ ground-truth (LiDAR) matches for $p_1(\rho)$ (green),
 - $4.2 \cdot 10^6$ random non-matches for $p_0(\rho)$ (red)

Obs:

- non-matches (red) may have arbitrarily large ρ
- matches (green) may have arbitrarily low ρ
- $\rho = 1$ is improbable for matches

Match Likelihood

- ρ is just a statistic
- we need a probability distribution on $[0, 1]$, e.g. Beta distribution

$$p_1(\rho) = \frac{1}{B(\alpha, \beta)} |\rho|^{\alpha-1} (1 - |\rho|)^{\beta-1}$$

- note that uniform distribution is obtained for $\alpha = \beta = 1$
- when $\alpha = 2$ and $\beta = 1$ then $p_1(\cdot) = 2|\rho|$

- the mode is at $\sqrt{\frac{\alpha-1}{\alpha+\beta-2}} \approx 0.9733$ for $\alpha = 10, \beta = 1.5$
- if we chose $\beta = 1$ then the mode was at $\rho = 1$
- perfect similarity is 'suspicious' (depends on expected camera noise level)
- from now on we will work with negative log-likelihood

$$V_1(\rho(l, r)) = -\log p_1(\rho(l, r)) \quad (35)$$

smaller is better

- we may also define similarity (and negative log-likelihood $V_0(\rho(l, r))$) for non-matches

► A Principled Approach to Matching

- given matching M what is the likelihood of observed data D ?
- data – all pairwise costs in matching table T
- matches – pairs $p_i = (l_i, r_i)$, $i = 1, \dots, n$
- matching: partitioning matching table T to matched M and excluded E pairs

$$T = M \cup E, \quad M \cap E = \emptyset$$

- matching cost (negative log-likelihood, smaller is better)

$$V(D | M) = \sum_{p \in M} V_1(D | p) + \sum_{p \in E} V_0(D | p)$$

$V_1(D | p)$ – negative log-probability of data D at matched pixel p (35)

$V_0(D | p)$ – ditto at unmatched pixel p

→170 and →171

- matching problem

$$M^* = \arg \min_{M \in \mathcal{M}(T)} V(D | M)$$

$\mathcal{M}(T)$ – the set of all matchings in table T

- symmetric: formulated over pairs, invariant to left \leftrightarrow right image swap

► (cont'd) Log-Likelihood Ratio

- we need to reduce matching to a standard polynomial-complexity problem
- we convert the matching cost to an 'easier' sum

$$\begin{aligned} V(D | M) &= \sum_{p \in M} V_1(D | p) + \sum_{p \in E} V_0(D | p) + \overbrace{\sum_{p \in M} V_0(D | p) - \sum_{p \in M} V_0(D | p)}^0 \\ &= \underbrace{\sum_{p \in M} (V_1(D | p) - V_0(D | p))}_{-L(D | p)} + \underbrace{\sum_{p \in E} V_0(D | p) + \sum_{p \in M} V_0(D | p)}_{\sum_{p \in T} V_0(D | p) = \text{const}} \end{aligned}$$

- hence

$$\arg \min_{M \in \mathcal{M}(T)} V(D | M) = \arg \max_{M \in \mathcal{M}(T)} \sum_{p \in M} L(D | p) \quad (36)$$

$L(D | p)$ – logarithm of matched-to-unmatched likelihood ratio (bigger is better)

why this way: we want to use maximum-likelihood but our measurement is all data D

- (36) is max-cost matching (maximum assignment) for the maximum-likelihood (ML) matching problem
 - use Hungarian (Munkres) algorithm and threshold the result with T : $L(D | p) > T \geq 0$
 - or step back: sacrifice symmetry to speed and use dynamic programming

Some Results for the Maximum-Likelihood (ML) Matching

- unlike the WTA we can efficiently control the density/accuracy tradeoff black = no match
- middle row: threshold T for $L(D | p)$ set to achieve error rate of 3% (and 61% density results)
- bottom row: threshold T set to achieve density of 76% (and 4.3% error rate results)

► Basic Stereoscopic Matching Models

- notice many small isolated errors in the ML matching
- we need a stronger model

$f(u, v)$

Potential models for M (from weaker to stronger)

1. Uniqueness: Every image point matches at most once

- excludes semi-transparent objects
- used by the ML matching algorithm (but not by the WTA algorithm)

2. Monotonicity: Matched pixel ordering is preserved

- For all $(i, j) \in M, (k, l) \in M, k > i \Rightarrow l > j$

Notation: $(i, j) \in M$ or $j = M(i)$ – left-image pixel i matches right-image pixel j

- excludes thin objects close to the cameras
- used by 3LDP [SP]

3. Coherence: Objects occupy well-defined 3D volumes

- concept by [Prazdny 85]
- algorithms are based on image/disparity map segmentation
- a popular model (segment-based, bilateral filtering and their successors)
- used by Stable Segmented 3LDP [Aksoy et al. PRRS 2008]

4. Continuity: There are no occlusions or self-occlusions

- too strong, except in some applications

Understanding Occlusion Structure in Matching Table

- this leads to the concept of 'forbidden zone'

► Formally: Uniqueness and Ordering in Matching Table T

$$p_j \notin X(p_i), \quad p_j \notin F(p_i)$$

- **Uniqueness Constraint:**

A set of pairs $M = \{p_i\}_{i=1}^n, p_i \in T$ is a matching iff

$$\forall p_i, p_j \in M : p_j \notin X(p_i).$$

X -zone, $p_i \notin X(p_i)$

- **Ordering Constraint:**

Matching M is monotonic iff

$$\forall p_i, p_j \in M : p_j \notin F(p_i).$$

F -zone, $p_i \notin F(p_i)$

- ordering constraint: matched points form a monotonic set in both images
- ordering is a powerful constraint: in $n \times n$ table we have monotonic matchings $O(4^n) \ll O(n!)$ all matchings

⊗ 2: how many are there maximal monotonic matchings? (e.g. 27 for $n = 4$; hard!)

- uniqueness constraint is a basic occlusion model
- ordering constraint is a weak continuity model and partly also an occlusion model
- monotonic matching can be found by **dynamic programming**

Some Results: AppleTree

left image

right image

ML \rightarrow 173

3LDP w/ordering
[SP]

naïve DP
[Cox et al. 1992]

Stable Segmented 3LDP
[Aksoy et al. PRRS 2008]

- 3LDP parameters α_i , V_e learned on Middlebury stereo data <http://vision.middlebury.edu/stereo/>

Some Results: Larch

left image

right image

ML →173

3DLP w/ordering [SP]

naïve DP

Stable Segmented 3DLP

- naïve DP does not model mutual occlusion
- but even 3DLP has errors in mutually occluded region
- Stable Segmented 3DLP has few errors in mutually occluded region since it uses a coherence model

Algorithm Comparison

Marroquin's Winner-Take-All (WTA →167)

- the ur-algorithm very weak model
- dense disparity map
- $O(N^3)$ algorithm, simple but it rarely works

Maximum Likelihood Matching (ML →173)

- semi-dense disparity map
- many small isolated errors
- models basic occlusion
- $O(N^3 \log(NV))$ algorithm max-flow by cost scaling

MAP with Min-Cost Labeled Path (3LDP)

- semi-dense disparity map
- models occlusion in flat, piecewise continuous scenes
- has 'illusions' if ordering does not hold
- $O(N^3)$ algorithm

Stable Segmented 3LDP

- better (fewer errors at any given density)
- $O(N^3 \log N)$ algorithm
- requires image segmentation itself a difficult task

- ROC-like curve captures the density/accuracy tradeoff
- numbers: AUC (smaller is better)
- GCS is the one used in the exercises
- more algorithms at <http://vision.middlebury.edu/stereo/> (good luck!)

Thank You

ROC curves and their average error rate bounds
